- 1 Linear Equations in Linear Algebra**
- 2 Matrix Algebra**
- 3 Determinants**
- 4 Vector Spaces**
- 5 Eigenvalues and Eigenvectors**

Eigenvalues and Eigenvectors appear in many systems, but concerning engineering, they appear in differential equations and continuous dynamical systems. These systems are another way to refer to difference equations. The dynamical system describes the linear transformations from one state to the next state, and the Eigenvalues and Eigenvectors help visualize and dissect these transformations.

5.1 Eigenvectors and Eigenvalues

An eigenvector of an $n \times n$ matrix A is a nonzero vector \mathbf{x} such that $A\mathbf{x} = \lambda\mathbf{x}$ for some scalar λ . A scalar λ is called an eigenvalue of A if there is a nontrivial solution \mathbf{x} of $A\mathbf{x} = \lambda\mathbf{x}$; such an \mathbf{x} is called an eigenvector corresponding to λ . λ is an eigenvalue of the $n \times n$ matrix A if and only if there is a nontrivial solution to the equation $(A - \lambda I)\mathbf{x} = \mathbf{0}$. The eigenspace is a subspace of the null space. Finding a basis for the eigenspace is the equivalent of solving the homogeneous equation just described and finding the vector equation corresponding to that solution. While this method works for finding the eigenvectors, the reduced echelon form does not showcase the eigenvalues. For there to be a nontrivial solution, to restate there needs to be linear dependence among the columns or free variables. One such case where eigenvalues can be found precisely is when you have a triangular matrix and the eigenvalues are the entries of the main diagonal. This is the case for the lower triangular matrices as well and repeats are treated as one eigenvalue. Zero can only be an eigenvalue of a matrix if that matrix is not invertible. If there is a set of eigenvectors that each correspond to a distinct eigenvalue, then these vectors are linearly independent. One simple way to solve the difference equations is to replace the previous state multiplied with the

matrix A by the matrix A multiplied with the initial state eigenvector multiplied with eigenvalue of this state to the previous states power. The transformation matrix raised to any power multiplied with \mathbf{x} is equivalent to the eigenvalue raised to the same power multiplied with \mathbf{x} . Multiples of eigenvalues are eigenvalues for the same scalar multiple of the matrix that the original eigenvalue was an eigenvalue for.

5.2 The Characteristic Equation

To find the eigenvalues for a given matrix, you must find λ values that will make the matrix not invertible. This is done by finding λ values that make the following true:

$$\det(A - \lambda I) = 0$$

Finding the roots of this equation yields the eigenvalues. This transformed the equation with two unknown in λ and \mathbf{x} into one with only one unknown in λ . To summarize previous findings, the determinant can be determined for higher order matrices by reducing to echelon form the matrix, and then multiplying -1 to the power of row interchanges needed by the pivot position values. If this value is 0, the matrix is not invertible. A scalar satisfying the above equation solves the characteristic equation. The degree of the characteristic equation is equivalent to the size of the matrix for an $n \times n$ matrix.

A matrix A is similar to the matrix B if there is an invertible matrix P such that $P^{-1}AP = B$ and this is referred to as the similarity transformation. If one matrix A and another B are similar, then they have the same characteristic polynomial and thus the same eigenvalues with the same multiplicities. Row operations normally change eigenvalues, so row equivalent matrices are not similar. Additionally, matrices with the same eigenvalues are not necessarily similar. Example 5 on Page 280 neatly explains the application of eigenvalues to dynamical systems. To get the expression for the initial state, find the scalar values that allow the eigenvectors to equate the initial state, thus giving you the full equation. All that was needed was the transformation matrix and the initial value of the system. Why the dynamical systems tend to a steady state value is that this steady state is a multiple of one of the eigenvectors for the matrix. The other eigenvectors drop out due to raising their λ values to an increasing power - so they trend to zero.

5.3 Diagonalization

If a given matrix is similar to a diagonal matrix, then this matrix is diagonalizable. For this to be true, the matrix has to have n (power of the matrix) linearly independent eigenvectors. Furthermore, the columns of P (used to determine similarity) must be n linearly independent eigenvectors of the matrix. For this case, the diagonal matrix has eigenvalues for A that correspond to the eigenvectors of P . In summary, there needs to be enough eigenvectors to form a basis of A . There are four steps for finding if a given matrix is diagonalizable:

- Find the eigenvalues of the given matrix by utilizing the characteristic equation and solving for the roots including multiplicities

- Find n linearly independent eigenvectors of the matrix by using the vector equation and the found eigenvalues
- Construct P from any combination of the eigenvectors as columns
- Construct D from the same order of eigenvalues in a diagonal matrix

If there are n eigenvalues for an $n \times n$ matrix, it is diagonalizable, but this is not a requirement as multiplicities can factor in as well. The k th power of the matrix is the Diagonalization of the matrix to the k th power with the similarity matrices on each side. The transformation matrix and the eigenvectors can be multiplied in order to determine the product of the eigenvalues and the eigenvectors to isolate the eigenvalues.

5.4 Eigenvectors and Linear Transformations

The linear transformation T onto \mathbf{x} can be viewed as left multiplication by the matrix M on the basis of \mathbf{x} . The matrix M is called the matrix for T relative to the bases β and ζ . In order to map this correctly, the β mapping to ζ through T needs to be understood. If this is the case, M is found by combining the columns of the mappings of the β components. If T is the identity matrix, then this reduces to a change of coordinates computation. When the dimensionality between the two spaces is the same and the coordinates for the bases are the same, then the mapping is referred to as the matrix for T relative to β . The images of the basis vectors are what the transformation for a given vector becomes. Basically for a polynomial, what the variable multiplied with the coefficients turns into after the transformation. From there, the β -coordinate vectors are how those transformations map into the original space based on the variables remaining.

If β is the basis for the space and formed by the P matrices from the diagonalization section, then D , the diagonal from that section, is the β -matrix. It is important to remember that any multiple of the eigenvectors through the free variable is considered a valid basis. Inversely, to find the beta matrix given the transformation matrix and the beta representations (P matrix), multiplying first by the inverse of P and then the transformation matrix, and then the P matrix yields the beta matrix. The Jordan form of the transformation matrix is a nondiagonal matrix that also is similar to the transformation matrix and thus also accurately describes the transformation.

5.5 Complex Eigenvalues

Let A be a real 2×2 matrix with a complex eigenvalue $\lambda = a - bi$ with b not being 0, and corresponding eigenvector \mathbf{v} , then $A = PCP^{-1}$ where $P = [\text{Re}\mathbf{v} \quad \text{Im}\mathbf{v}]$

$$C = \begin{bmatrix} a & -b \\ b & a \end{bmatrix}$$

5.6 Discrete Dynamical Systems

When you have all of the eigenvalues of a system less than one, the origin (or point where the equation approaches) is called an attractor and the direction of greatest

attraction is along the line through the zero vector and the eigenvector for the smaller eigenvalue. The opposite is true when both eigenvalues are greater than 1, being a repeller, and the direction of repellant is along the line through the zero vector and the eigenvector of the larger eigenvalue. Rejection and attraction are determined in the same way, and the saddle point is the location that movement is from. For matrices that are not diagonal, a change of variable and some algebra produce a matrix that utilizes only diagonals. A similar interpretation is made when there are complex eigenvalues and eigenvectors. If the absolute value of the eigenvalues is greater than 1, then the zero vector is a repeller and the iterates of the initial vector spiral outwards from the origin. The opposite is true if the absolute value of the eigenvalues is less than 1. Given a dynamical system and an initial value, solving for the coefficients is done with the initial state and eigenvectors, and from there the dynamical system is made from the eigenvalues, coefficients, and eigenvectors.

5.7 Applications to Differential Equations

Eigenvalue-eigenvector pairs form solutions to the differential equation. Exponentials are necessary in this case as the derivative of the exponential will help to maintain the equality of the derivative equaling the matrix multiplied with the vector that is differentiated. Combining the eigenfunctions with the initial values works to yield the coefficients for the solutions. Complex eigenvalue-eigenvector pairs can be mapped into the real realm for solutions to the differential equations through the following expansions:

$$e^{(a+bi)t} = e^{at} + e^{ibt} = e^{at}(\cos(bt) + i\sin(bt))$$

From there, the following equations show the solutions after the change in variable for any dimensionality:

$$\begin{aligned} \mathbf{y}_1(\mathbf{t}) &= \text{Re}\mathbf{x}_1(\mathbf{t}) = [(\text{Re}\mathbf{v})\cos(bt) - (\text{Im}\mathbf{v})\sin(bt)]e^{at} \\ \mathbf{y}_2(\mathbf{t}) &= \text{Im}\mathbf{x}_1(\mathbf{t}) = [(\text{Re}\mathbf{v})\sin(bt) + (\text{Im}\mathbf{v})\cos(bt)]e^{at} \end{aligned}$$

Spiral points are another means to describe graphically what the solution space is doing and are a result of the trigonometric properties of the solutions from the complex eigenvalues.

5.8 Iterative Estimates for Eigenvalues

An approximation for the dominant eigenvalue can be found in 5.8 on page 323 through Example 1. Multiplying the initial matrix with the initial state and scaling by the largest absolute value term yields the approximate largest eigenvalue and an eigenvector over time. The rate of convergence for this method depends on the ratio of the eigenvalues. For finding any eigenvalue, using the inverse power method with rough estimates for the eigenvalues can find you solutions to certain degrees of certainty. If there is no known estimate, zero can be used as an initial eigenvalue estimate to find the smallest eigenvalue. QR methods are more advanced and are used by Matlab in order to implement the same functionality as described here.
